3 **1 Abstract**
4

5 Forest canopies represent an extensive organic surface available for partitioning of
6 semivolatile organic pollutants with the atmosphere. To date, the ability of forests to
7 sequester such compounds (the so called “forest filter effect”) has been investigated using
8 indirect methods which yield time integrated deposition fluxes and scenario-dependent
9 deposition velocities. In the present study, experimental data collected at three different
10 alpine forest sites were used to assess the dynamics of PCB deposition fluxes (F ; $\text{ng m}^{-2}\text{d}^{-1}$)
11 during the growing season. Estimated values of F were consistent with previously
12 reported data. Furthermore, this study showed that maximum levels of F in late spring
13 can be a factor of 1.4-3.4 higher than their seasonal mean value. These data, in
14 conjunction with a simple model framework which includes the main forcing parameters
15 of air concentration, temperature, foliage structure and biomass dynamics, are used to
16 estimate the plant-air mass transfer coefficient (k_U ; m d^{-1}) and its variation with time in
17 one of the forests. k_U did not appear to significantly vary during the season and its mean
18 seasonal value ranged between 43-95 m d^{-1} for selected compounds. The proposed
19 framework was successfully applied to predict the variation in canopy concentration with
20 time in the other two forests.

1 Introduction

2 Persistent organic pollutants (POPs) can undergo long range atmospheric transport
3 following emissions in source areas (1, 2). During their journey, these pollutants partition
4 to available environmental media, including soils (3), water bodies (4) and vegetation (5).
5 Because of their lipophilicity, the environmental stocks of organic carbon play a key role
6 in this partitioning of POPs (6). Vegetation provides an important, carbon rich interface
7 with which POPs interact (5, 7) given plant foliage efficiently accumulates compounds
8 with $\text{Log}K_{OA} > 6$ and $\text{Log}K_{AW} > -6$ (8) from the atmosphere, showing bio-concentration
9 factors or equilibrium plant-air partition coefficients (K_{PA} , defined on a volume/volume
10 base) in the order of 10^6 - 10^8 (9-11).

11 Forests cover approximately one-third of the world's land area (12) and form one of the
12 world's largest organic carbon stocks (13, 14). This, allied to their large unit area
13 standing biomass and high carbon turnover rates, means that forest canopies have the
14 potential to affect air-surface POP partitioning significantly. In a mature forest canopy,
15 there is as much as 8 - 10 m² of organic leaf surface per unit of ground area which is
16 available for POP exchange with air (15). In addition, the organic carbon pool of the
17 forest canopy is structurally organized to optimize light harvesting and gas exchange
18 (16), thereby inadvertently enhancing the rate of air-leaf gaseous exchange of POPs (17).

19 Horstmann and McLachlan (18,19) investigated the air-canopy exchange of POPs and
20 showed that yearly averaged deposition fluxes to forest soils were 3-5 times higher than
21 to bare soils. Additional experimental confirmation of this effect was obtained more
22 recently (20, 21). Using these results, some global scale model assessments have been
23 performed which, through arbitrarily attributing annual POP deposition velocities for
24 different forests types (22-24), indicated that the presence of vegetation can significantly
25 affect the global distribution of POPs (22-24). However, for regions experiencing
26 significant seasonality, 'yearly averaged' characterisation of air-canopy exchange of
27 POPs such as these ignore the potentially important effects of intra-annual changes in
28 forest composition, biomass, boundary layer and surface roughness. To understand the
29 importance of these dynamic effects requires studies which are able to resolve this

1 temporal variability at the forest scale. To date, such studies have been notable by their
2 absence in the POP literature.

3 This paper exploits a simple mass balance framework accounting for the role of
4 vegetation structure, temperature and biomass growth, combined with data from a recent
5 field study reporting the accumulation of POPs in the leaves of two alpine forests (11)
6 over a single growing season, to attempt to resolve the temporal evolution of the air-
7 canopy exchange flux of POPs, F ($\text{ng m}^{-2} \text{d}^{-1}$) and the effective air-canopy mass transfer
8 coefficient, k_u (m d^{-1}).

9

10 **Methods**

11 ***Data source***

12 Nizzetto *et al.* (11) provide experimental data from a field campaign performed in April-
13 October 2005 where a range of PCBs were measured in the atmosphere and vegetation of
14 two Italian alpine broadleaved forests, with one at 1100 m the other at 1400 m altitude
15 (referred to as the 1100 and 1400 m site, hereafter). During the same period data were
16 also collected in a third forest site located at an altitude of 1800 m on the same slope
17 comprised exclusively of larch (*Larix deciduas*), a deciduous conifer. Figure SI 1 shows
18 the forest composition and structure of the sites and Text SI 1 describes the
19 characteristics of the dataset and provides some considerations of the spatial scale and the
20 significance of the present calculations. Available data include: PCB canopy
21 concentration (C_C ; $\text{pg g}^{-1} \text{dw}$); air concentrations (C_A , pg m^{-3}); leaf area index (LAI ; $\text{m}^2 \text{m}^{-2}$,
22 referring to 1 side of the leaf); mean canopy specific leaf area (SLA_C ; $\text{m}^2 \text{g}^{-1} \text{dw}$,
23 referring to 1 side of the leaf); data on forest composition, and air temperature (T).
24 Additionally ref. 11 reports estimates of the equilibrium leaf-air partition coefficients
25 (K_{PA} ; m^3 of air per g of leaf dw) for the dominant tree in the forest sites.

1

2 ***Estimation of POP fluxes to the canopy, F***

3 Because of the discrete, unevenly sampled nature of the canopy characteristics
 4 measurements, experimental results for C_C , LAI and SLA were interpolated using low
 5 order polynomials (Figure 1). This allowed the functions describing their seasonal
 6 variability to be obtained on a daily resolution, and time derivatives to be calculated.

7 The accumulation of POP in the canopy per unit of ground surface at a given time, U (ng
 8 m^{-2}) is given by,

$$9 \quad U = BC_C = \frac{LAI}{SLA_c} C_C \times \frac{1}{1000} \quad 1)$$

10 where B is the canopy biomass ($g\ m^{-2}$, dw) and 1000 is the scaling factor which provides
 11 the correct unit fo U . Finally, $F = dU/dt$ ($ng\ m^{-2}\ d^{-1}$)

12 ***Effective air-canopy mass transfer coefficient estimates, k_u***

13 The accumulation of atmospheric POPs by vegetation can be described by considering
 14 the forest canopy as a single homogenous compartment in contact with the air, with
 15 diffusive exchange of POPs between the air and the canopy described by a standard linear
 16 gradient analogue. Thus, the air-canopy exchange flux of POPs, F can be described as
 17 follows (16):

$$18 \quad F = k_u 2LAI \left(C_A - \frac{C_C}{K_{PA}} \right) \quad 2)$$

19 Obviously equation 2 only attempts to describe the uptake of gaseous compounds and not
 20 of those associated to particles. However, it was shown that in these sites the particle
 21 phase concentration of the selected compounds is negligible (11, 25). The coefficient 2 is
 22 needed to account for both the sides of the leaves (see above).

23 Although conceptually simple, equation 2 captures both the mass transport characteristics
 24 of the air-canopy exchange in addition to the effects of canopy growth dilution on C_c .
 25 Remembering the definition of F , equation 2 can be rewritten as follows:

$$1 \quad \frac{dC_C}{dt} = k_U 2SLA_C \left(C_A - \frac{C_C}{K_{PA}} \right) - k_G C_C \quad 3)$$

2 with $SLA_C = \frac{LAI}{B}$ and k_G (the growth dilution rate, d^{-1}) defined as $\frac{dB}{dt} \frac{1}{B}$.

3 In summary, the following assumptions have been made in the present analysis:

- 4 i) Given the small proportion of the atmospheric PCB which is particle bound
5 (11-25), aerosol deposition (wet and dry) onto canopy surfaces was assumed
6 to be negligible;
- 7 ii) During the sampling campaign precipitation averaged 500 mm (21). Even
8 assuming a worst case scenario (i.e: that this amount of water is at equilibrium
9 partitioning with the atmosphere and that after the impact with the canopy
10 surface, the load of pollutants is instantaneously transferred to the leaves) wet
11 deposition is not expected to produce any significant effect on C_C and hence
12 has been ignored
- 13 iii) because the time frame of the study only covered the active growing season,
14 and taking into account the persistence and hydrophobicity of the chemicals
15 being considered (26), loss of POPs from the canopy due to reaction or wash-
16 out is negligible;
- 17 iv) POP loss from the canopy due to cuticular wax erosion has been hypothesized
18 in previous studies (18, 21) although it is not clear if this can significantly
19 influence canopy PCB concentration in deciduous forests. This loss process
20 are driven primarily by a leaf mass export from the canopy. Recent studies
21 (27, 28) showed that only a small fraction of the total PCBs in the leaf foliage
22 is expected to be stored in cuticular waxes. Finally, it has been shown that the
23 total deposition of PCBs during spring and summer is negligible compared to
24 the litter fall period in deciduous stands (20).

1
2
3 1 v) Although non-leaf surfaces (i.e. tree bark and soil) can also accumulate
4 significant amounts of POPs directly from the atmosphere (29), these are
5 2 considered negligible compared to that accumulated by foliage, given the
6 3 latter's larger surface area (18, 21) and that changes in bark mass are very
7 4 small compared to changes in leaf area.
8 5

13 6 Providing K_{PA} is known, all terms in equation 2 are known other than k_U which can, as a
14 7 result, be determined. Ref. 11 reports estimates of K_{PA} values for the dominant species at
15 8 the 1100 m and 1400 m forests. These values were derived based on the same dataset
16 9 used in the present study to calculate F . In order to estimate k_U , it is important to use
17 10 values derived from an independent dataset. For this reason, the K_{PA} values estimated for
18 11 larch at the 1400 m site (11) were used in equation 1 together with C_C and the biophysical
19 12 parameters of the larch stand at 1800 m (figure 1) to derive the k_U value for this site. The
20 13 effect of temperature on K_{PA} was accounted for using the Van't Hoff equation with the
21 14 enthalpy of plant-air phase transfer taken from ref. 30.

30 15 *Propagation of uncertainties*

33 16 The propagation of uncertainty was assessed using a simple Monte Carlo framework. The
34 17 uncertainty in C_C and SLA_C estimates were assumed to be represented by the covariance
35 18 matrix estimates of the polynomial parameters when fitted to the observed time series
36 19 data in Figure 1. The uncertainty on LAI was obtained from the standard deviation of
37 20 repeated ($n = 10$) measurements (11). The uncertainty in the measured C_A values was
38 21 assumed to be described by the relative standard deviation of the reproducibility study
39 22 presented in ref. 25. Finally, the uncertainty on K_{PA} estimates was that reported in ref. 11.

46 23 To translate these uncertainties into the final estimates of F and k_U , $N = 10^4$ repeat
47 24 calculations were made for each time-step. For each calculation the observed terms in
48 25 equations 1 and 2 were generated using the polynomial parameter combinations drawn
49 26 randomly from the relevant covariance matrix, assuming normality in all cases.

1 Results

2 Figure 1 shows the least squares fits of low order polynomials used to capture the
3 seasonal trends in the experimental observations. Calculations were performed for PCBs
4 101, 118, 138, 153 and 180 (as an example Figure 1 shows results for PCB 138 at the
5 1800 m site). This approach was not suitable to describe the behaviour of C_C for tri- and
6 tetra-CB which showed more complex/uncertain dynamics (11). Therefore, these
7 compounds were not considered in the present study. All variations in the observed terms
8 with frequencies higher than the seasonal trend described by the polynomial fits are
9 treated as noise. Thus the present approach only attempts to capture seasonality when
10 estimating F and k_U .

11 *PCB air-canopy exchange flux (F)*

12 Figure 2 shows estimates of F derived for PCB 138 at the three forest sites. F was
13 maximum in late spring, when a considerable amount of leaf biomass was already
14 available for exchange, but C_C was still far from reaching partitioning equilibrium. F
15 tended to decrease after this, reaching a minimum in mid summer when higher
16 temperatures inhibited the canopy capacity for taking up POPs from the air. Similar
17 behavior was previously described in a model simulation of the canopy uptake of POPs
18 (31).

19 After this period, the estimates of C_C and B derived from the associated polynomials
20 introduced significant uncertainty into the estimates of F , preventing any meaningful
21 analysis. However, F is expected to tend to zero when the canopy approaches equilibrium
22 partitioning with the air, although the decrease in temperature occurring at the end of the
23 season could have enhanced deposition fluxes until litter fall. Given the large amount of
24 leaf surface available at this stage, this effect could generate significant late season
25 deposition fluxes. During the spring maximum (i.e the period of leaf growth), F for PCB
26 138 reached 0.9-1.1, 0.8-1.5, and 0.8-1.6 $\text{ng m}^{-2} \text{d}^{-1}$ for the 1100, 1400 and 1800 m sites
27 respectively. Table 1 reports overall mean and peak F values for other selected
28 compounds. These fluxes are high but consistent with previously reported data obtained
29 using deposimeters (20) although the estimates made here have resolved their seasonality,
30 showing maximum daily F values a factor 1.4-3.4 higher than the overall mean value.

1 *Air-canopy mass transfer coefficient (k_U)*

2 The k_U estimates obtained here can be regarded as a measure of the average overall mass
3 transfer coefficient for PCBs between air and vegetation (per unit of leaf surface) at the
4 canopy spatial scale and on a time scale of weeks. Therefore, differences due to
5 particularly dynamic atmospheric conditions (i.e. storms, strong wind speeds, diel
6 variability of the turbulence in the atmospheric boundary layer) will not emerge from the
7 dataset.

8 Results of the calculation of k_U for PCB 138 are reported in Figure 3 as an example.
9 Considering the uncertainty amplified when rearranging equation (2), no significant
10 seasonal trends were observed. However, there appears to be a tendency (especially
11 observed for PCB 138, 153 and 180), toward high median values coinciding with the
12 phase of biomass development and lower values during the warmest part of the year.
13 After the end of June the estimation of k_U became compromised during certain periods.
14 This was mainly dependent ($P < 0.05$) on the value of the concentration gradient
15 $\left(C_A - \frac{C_C}{K_{PA}} \right)$ tending to zero and hence generating critical numerical limits when
16 rearranging equation 2. This not only occurred as the canopy approached equilibrium, but
17 also in warmer conditions because the concentration gradient is negatively correlated to
18 the temperature. It is possible to show that when the vegetation reaches 65 percent POP
19 saturation the quality of the estimates of k_U generally drops (see figure SI2).

20 During August-September when the canopy POP saturation is high, the value of the
21 concentration gradient is mainly influenced by the temperature dependence of K_{PA} .
22 Given there is no reason to expect that k_U falls close to zero in August and September,
23 these low values are probably a result of the fact that the temperature dependence of the
24 larch needle K_{PA} is different from that assumed from ref. 30 highlighting an area that
25 needs developing in the analysis. At the beginning of the season the k_U estimates are
26 much less influenced by this possible artefact because the level of equilibrium saturation
27 is still low. Despite this limitation, the median value of k_U was always the same order of
28 magnitude as the seasonal mean value.

1 The best estimates of k_U were mainly obtained between May and the end of June when
2 C_C was still far from approaching partitioning equilibrium. In this phase, the 95 percent
3 confidence interval on the k_U estimates was approximately a factor of 2 around the
4 median values. The overall means of k_U values calculated for selected compounds in the
5 period between 2 May -16 June are reported in Figure 3 and ranged between 43-95 m d^{-1} .
6 Considering the uncertainty, no significant differences ($P < 0.05$) were observed among
7 different compounds.

8 Other studies attempted to provide estimates of the POP transfer rate between the air and
9 the forest canopy (18-21) in the form of mean seasonal deposition velocities v (m d^{-1}).
10 Remembering its definition (18) v can be regarded as the velocity of the transfer of POPs
11 between air and the forest per unit of ground surface. The value of v estimated for
12 selected compounds has been reported previously for the same forest canopy at 1800 m
13 site (21). This was obtained using deposimeters, a method that can account for the effect
14 of different loss processes from the canopy (i.e. wax erosion and wash out). It is possible
15 to show that for compounds which do not reach the partitioning equilibrium within the
16 growing season

$$v = 2LAI(\overline{k_U}) \quad 4)$$

17
18 where $\overline{k_U}$ is the mean seasonal value of k_U . Using the data of PCB 180 (a congener that
19 did not reach partitioning equilibrium (11) as an example) good agreement is obtained
20 between the estimated value of v through equation 4 (620 m d^{-1} ranging $390 - 850 \text{ m d}^{-1}$)
21 and the one measured (590 m d^{-1}) (21). This supports the aforementioned assumption
22 regarding loss processes.

23 A limitation in estimating k_U using the present approach is the need to know the value of
24 K_{PA} a priori. There is still only limited K_{PA} data for specific canopies (11, 18, 20).
25 However, under the conditions of this study, the adopted framework is not particularly
26 influenced by the uncertainty on the K_{PA} value. In fact, even adopting values reported for
27 other forests/species (18, 20) (which, once corrected for temperature are higher by a

1
2
3 1 factor ~ 4 compared to that used here) the seasonal mean value of k_U only changes by
4
5 2 about 20%.
6
7
8 3

10 4 ***Testing the predictive capability of the modelling framework***

11 5 The proposed framework was tested by comparing predicted and observed C_C values in
12 6 the 1100 and 1400 m forests, over time. Calculations were performed using equation 3 by
13 7 introducing the seasonal mean value of k_U derived from the 1800 m site data for selected
14 8 compounds (Figure 3). Given that the 1100 m and 1400 m sites are multi-species forests,
15 9 the adopted K_{PA} value for the prediction represented the weighted average of the
16 10 dominant species, aggregated as a function of their relative abundance in the canopy. The
17 11 reported experimental C_C values therefore also represent the mean canopy concentrations.
18 12 Text SI 2 explains the method used for determining the forest composition, while Figure
19 13 SII schematizes forest composition and structures.

20 14 The performance of the predictions is reported in Figure 4. Predictions successfully
21 15 described the experimental observations at both sites. The ratio between predicted and
22 16 observed C_C for all the considered compounds was 1.06 ± 0.46 and 1.03 ± 0.21 at the 1100
23 17 m and 1400 m sites, respectively. Standard sensitivity analysis showed that the most
24 18 influential parameters in determining C_C were k_U and SLA . Despite this, equation 3
25 19 successfully predicted C_C for forest canopies with different structures (e.g. SLA_C varied
26 20 by a factor of 2 between the 1400 m and the 1800 m sites and maximum LAI ranged
27 21 between 4.1 and 5.4) and under different temperature conditions (mean seasonal
28 22 temperature ranged at the three sites between 17 and 12°C).

29 23 30 24 ***Further work***

31 25 The framework presented here offers an extension to the somewhat static analyses of air-
32 26 canopy POP exchange presented to date (18, 20, 21, 32) by attempting to recover the
33 27 seasonal characteristics of F and k_U for an Alpine forest area. One obvious limitation of
34 28 the present framework is the need to assume values of K_{PA} a priori, whereas it is clear

1 from equation 2 that identifying this value is in fact part of the problem. Fortunately, in
2 relation to the present results, the sensitivity analysis indicates that the current framework
3 is not sensitive to this when the canopy is far from the partitioning equilibrium.

4 Both the framework and the results from this study should be useful when incorporating
5 vegetation compartments in regional or global fate dynamic models. Additionally, given
6 the intimate association between the canopy carbon stock and POP turnover shown here,
7 studies such as this should seek to further exploit the extensive network of tower-based
8 carbon flux monitoring sites (33) when developing POP modelling and monitoring
9 programs.

1 **Table 1.** Calculated values of U_{max} (ng m^{-2}), mean and max F ($\text{ng m}^{-2} \text{d}^{-1}$) for selected
 2 compounds. U_{max} is the maximum reached amount of a given compound sequestered in
 3 the canopy.

4

	1100 m			1400 m			1800 m		
	U (max)	F (mean)	F (max)	U (max)	F (mean)	F (max)	U (max)	F (mean)	F (max)
PCB 101	108	0.62	0.87	126	0.63	1.05	174	1.09	2.69
PCB 118	64	0.26	0.45	50	0.34	0.72	79	0.46	0.98
PCB 138	97	0.70	1.04	126	0.70	1.05	123	0.74	1.69
PCB 153	161	1.05	1.64	84	0.67	1.51	144	0.84	2.87
PCB 180	66	0.39	0.58	43	0.34	0.65	65	0.38	0.65

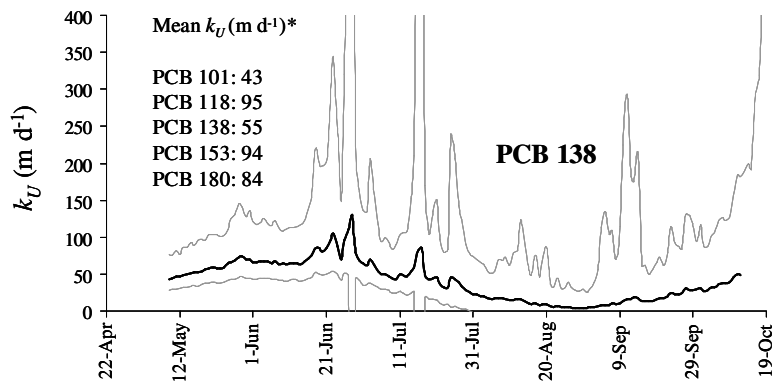

1

2 **Figure 1.** Experimental and modeled parameters for the calculation of k_U . The figure
 3 presents data for PCB 138 and the properties of the 1800m forest. Dots are experimental
 4 observations (11), the black line represents the median optimum fitted value of the
 5 modeled parameters, grey lines are 95% confidence interval. Blue lines in the C_A plot are
 6 measured mean values (11, 25).

1

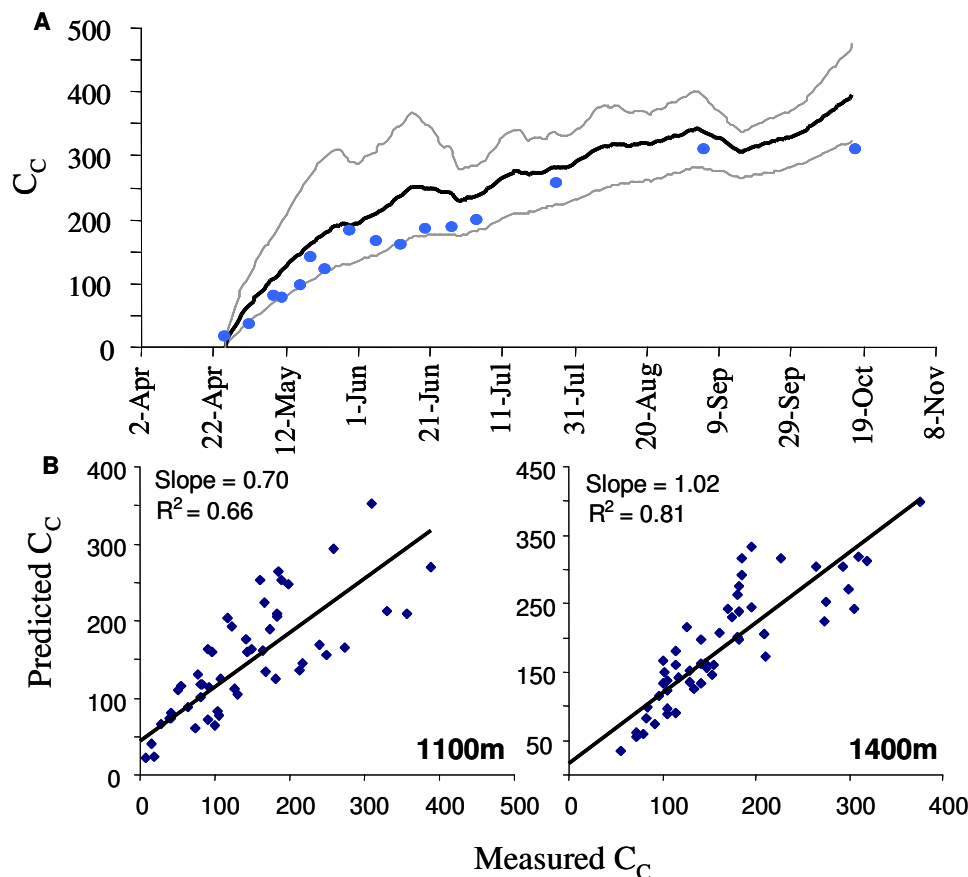

2 **Figure 2.** Plots to show how the amount (U) and the air-canopy exchange flux (F) vary
3 seasonally for the two forested sites using as an example PCB 138. Note: the black line is
4 the median, grey lines represent the 95% confidence boundaries.

1

2 **Figure 3.** Derived values of k_U through the season at the 1800 m site (the example refers
3 to the calculation for PCB 138). The median value is shown in black, while the grey lines
4 represent the 95% confidence bounds of $N = 10^4$ Monte Carlo simulations.

5 * Averal mean for the best estimates (2 May- 16 June).

1

2 **Figure 4:** Assessment of the predictive ability for equation 2. A: comparison between
 3 experimental C_C ($\text{pg g}^{-1} \text{ dw}$) (points) and predicted C_C with time (black line: median of
 4 the predictions; grey line 95% boundaries of predictions). Data refers to PCB 138 in the
 5 1100 m forest. B: Predicted C_C ($\text{pg g}^{-1} \text{ dw}$) vs observed for the 1100 m and 1400 m forest
 6 sites. Figure includes results for PCB: 101, 118, 138, 153 and 180. Calculations were
 7 performed using the seasonal mean k_U values reported in Figure 3.
